Seasonal variation of surface and air temperatures across a range of plant functional types and climatic zones

Lead author: Youngryel Ryu (UC Berkeley)

Background and Significance

Surface temperature ($T_{sfc}$) and the difference between $T_{sfc}$ and air temperature ($\Delta T$) control the biological function (e.g. photosynthesis, respiration, phenology) and energy balance (e.g. sensible, latent, ground heat fluxes and net radiation) of the land surface. Recently, Helliker and Richter (2008) inferred growing season leaf temperature from stable isotope analysis, and found it to be virtually constant at around 21°C from boreal to sub-tropical climatic zones. Now that the FLUXNET database provides aerodynamic surface temperature ($T_{sfc(a)}$) from sonic anemometers and radiometric surface temperature ($T_{sfc(r)}$) from four-band radiometers, it is feasible to investigate the seasonal variation of $T_{sfc}$ and $\Delta T$ across a range of plant functional types (PFT) and climatic zones to investigate the canopy temperature convergence hypothesis of Helliker and Richter (2008) and better-quantify the influence of vegetation on the temperature of the Earth’s surface.

$T_{sfc}$ and $\Delta T$ are also important for the remote sensing of evapotranspiration. The land surface energy balance ($\lambda E = R_n - H - G$) or Penman-Monteith equation have been widely used in remote sensing, but special attention is required to accurately quantify the relationship between surface temperature and the terms of the energy balance to which $T_{sfc}$ is coupled. For the first approach, sensible heat flux ($H$) has been inferred from thermal remote sensing, but $T_{sfc(r)}$ can be different from $T_{sfc(a)}$ by 2-6 °C (Huband and Monteith 1986), leading to errors in $H$ estimates. Differences in the temperature terms across a range of PFT could be quantified using FLUXNET database to benefit the remote sensing community. For the second approach, it should be noted that P-M approaches used first order Taylor expansion for estimating saturation vapor pressure at $T_{sfc}$. This assumption is only valid when $\Delta T$ is very small. If $\Delta T$ is greater than 5°C, it could cause large error in estimating evapotranspiration (Paw U and Gao 1988). Quantification of $\Delta T$ across a range of PFT and climate types will reduce errors in evapotranspiration estimates under conditions where the P-M equation is not valid.

Objectives

1. Investigate the seasonal variation of $T_{sfc}$ and $\Delta T$, and their implications on ecophysiology in global ecosystems.
2. Quantify the difference between $T_{sfc(r)}$ and $T_{sfc(a)}$ across global PFTs.

An example for Vaira ranch

Expected sites

Sites that have at least one-year good data of sensible heat flux, air temperature and four-band radiation data will be considered in this project.
